ABSTRACT

Objective: Most patients with atrial fibrillation (AF) have risk factors and coexisting conditions that increase their mortality risk. We performed a cause-of-death analysis to identify predictors of mortality in hospitalised patients with AF in France.

Methods and results: In this retrospective, population-based cross-sectional study, the *Programme de médicalisation des systèmes d'information* was used to identify 533 044 adults with a diagnosis of AF or atrial flutter hospitalised for any reason in France from January through December 2012. Stepwise multivariable analyses were performed to identify determinants of mortality. The mean age was 78.0±11.4 years, 47.1% were women, and the mean CHA₂DS₂-VASc score was 4.0±1.8. During hospitalisation, 9.4% (n=50 165) of the patients died, 34% due to a cardiovascular event, most often heart failure (16.6%), stroke/transient ischaemic attack/systemic embolism (9.8%) or vascular or ischaemic disease (4.0%). The strongest predictors of overall death were age ≥75 years (OR 2.57, 95% CI 2.47 to 2.68), renal failure (OR 1.85, 95% CI 1.81 to 1.89), cancer (OR 1.81, 95% CI 1.78 to 1.85) and lung disease (OR 1.58, 95% CI 1.55 to 1.62).

Conclusions: Cardiovascular events were the most common cause of death, occurring in one-third of patients, in this comprehensive study of hospitalised patients with AF. Despite the high risk of stroke in this population, only 10% died from stroke/transient ischaemic attack/systemic embolism. The strongest predictors of overall death were non-cardiovascular. Physicians should be encouraged to focus on preventable serious and disabling cardiovascular events (such as stroke) as well as on potentially fatal non-cardiovascular comorbidities.

INTRODUCTION

Atrial fibrillation (AF) is the most common chronic cardiac rhythm disorder, with a prevalence of between 1% and 2% in the general population.¹ Between 600 000 and 1 million people in France are estimated to have AF,² and the prevalence is rising.^{3 4} AF

KEY QUESTIONS

What is already known about this subject?

- Most patients with atrial fibrillation (AF) have risk factors and coexisting conditions that increase their mortality risk, but the mode of death in patients with AF is poorly understood.

What does this study add?

- Cardiovascular events were the most common cause of death (34% of cases) in this comprehensive study of hospitalised patients with AF.
- Ten per cent of the patients died from stroke/transient ischaemic attack/systemic embolism.
- The strongest predictors of overall death were non-cardiovascular: age ≥75 years, renal failure, cancer and lung disease.

How might this impact on clinical practice?

- Physicians in charge of the management of patients with AF should be encouraged to focus not only on preventable serious and disabling cardiovascular events (such as stroke) but also on other potentially fatal non-cardiovascular comorbidities.

is associated with a 1.5-fold mortality risk in men and a 2-fold risk in women, after adjustment for associated cardiovascular conditions.⁵ The Women's Health Study, in an analysis of 34 722 initially healthy women, showed that new-onset AF is independently associated with cardiovascular, non-cardiovascular and all-cause mortality.⁶ AF is also associated with worse clinical outcomes in many cardiovascular disease states.^{7–9} Patients with AF are at fivefold increased risk of ischaemic or haemorrhagic stroke.¹⁰ The severity of the stroke is greater compared with strokes unrelated to AF,⁷ and the 30-day mortality rate is higher.⁷ An analysis from a French national database estimated that 21.6% of patients with AF who are hospitalised due to an ischaemic or haemorrhagic stroke die during hospitalisation.¹¹

Most patients with AF have cardiovascular risk factors and coexisting conditions that increase their mortality risk,^{4 6} but the mode of death in patients with AF is poorly understood. Predictors of mortality were identified using data from the Randomized Evaluation of Long-Term Anticoagulant Therapy (RE-LY) trial, which compared dabigatran with vitamin K antagonists in >18 000 patients with AF.¹² The strongest predictors of cardiac death were heart failure, previous myocardial infarction, abnormal conduction and reduced renal function. Stroke accounted for only 11.4% of cardiovascular deaths. The applicability of the RE-LY study findings, conducted within the confines of a selected clinical trial population (in which oral anticoagulation was systematically used), to patients with AF treated in everyday clinical practice, is uncertain. There is, therefore, a need to better understand the AF population in order to identify specific interventions that could reduce the mortality risk associated with this increasingly prevalent arrhythmia.

The aims of this study were twofold: to identify the characteristics of patients hospitalised with AF in France; and to perform a cause-of-death analysis to identify predictors of overall mortality, and mortality due to heart failure, ischaemic stroke and intracranial haemorrhage.

METHODS

BALZAC (Burden of cArديوascuLar hospitaliZations in patients with Atrial fibrillation in FranCe) was a retrospective, population-based cross-sectional study. We used data from the *Programme de médicalisation des systèmes d'information* (PMSI), which comprises national comprehensive databases that record diagnoses and procedures for all day care and inpatient stays in private and public hospitals in France. PMSI has previously been used to study patients with stroke,¹³ myocardial infarction¹⁴ and AF.²

This study was conducted in accordance with International Society for Pharmacoepidemiology Guidelines for Good Pharmacoepidemiology Practices and applicable regulatory requirements. The study was approved by the Commission Nationale Informatique et Liberté (National Commission for Data Protection and the Liberties), the independent National ethical committee protecting human rights in France, including those of patients. As a retrospective observational analysis from a national database, patient informed consent was not obtained. Procedures for data collection and management were approved by the Conseil National de l'Informatique et des Libertés, which ensures that all medical information is kept confidential and anonymous.

The study population comprised adults (≥18 years) with a diagnosis of AF or atrial flutter (see online supplementary table S1 for the International Classification of Disease 10th edition (ICD-10) codes) coded in the principal diagnosis (ie, the health problem that justified admission to hospital, and coded at discharge), the

related diagnosis (ie, potential chronic disease or health state during hospital stay) or the significantly associated diagnosis (ie, comorbidity or associated complication), who were hospitalised for any reason from 1 January to 31 December 2012. Patient information (demographics, comorbid conditions, medical history and death during hospitalisation, if it occurred in 2012) is described using data collected in their hospital records since 1 January 2007.

Individualised risk stratification was performed retrospectively using the CHA₂DS₂-VASc (Cardiac failure or dysfunction, Hypertension, Age ≥75 years (Doubled), Diabetes, Stroke (Doubled)-Vascular disease, Age 65–74 years and Sex category (Female))¹⁵ score for stroke and the HAS-BLED (Hypertension, Abnormal renal/liver function, Stroke, Bleeding history or predisposition, Labile international normalised ratio (INR), Elderly (>65 years), Drugs/alcohol concomitantly)¹⁶ score for bleeding. As not all components of the HAS-BLED score were available, a modified version¹⁷ (excluding labile INR and antithrombotic drug therapy) is presented. Patients who died in hospital (including in a rehabilitation centre) were identified through their discharge summary, and each in-hospital death was attributed to one cause exclusively (ie, the principal diagnosis for the hospitalisation when death occurred).

Statistical analysis

Categorical variables are described using counts and percentages, and continuous quantitative variables as means and SDs or medians (IQRs), as appropriate. Clinical parameters of patients with AF alive and dead at discharge for any reasons were compared, as well as for a patient with AF suffering from three specific types of event: heart failure, ischaemic stroke and intracranial haemorrhage. Intergroup differences were assessed using the χ^2 test for categorical variables and Student's t test or the Mann-Whitney U test for continuous variables. To identify predictors of death, multiple logistic regression analyses based on a forward stepwise method adjusted for age, sex and all clinical variables with $p < 0.05$ in the univariate analysis were performed. ORs and 95% CIs were calculated. In all analyses, a value of $p < 0.05$ was considered statistically significant. To further take into account a possible sex and age period interaction, we performed interaction tests. All analyses were performed using SAS software V.9.2 (Cary, North Carolina, USA).

RESULTS

Hospitalised patients with AF

In France, in 2012, 533 044 patients were hospitalised with AF as the principal, related or associated diagnosis. The mean number of hospitalisations per patient was 1.53 (1.64 for patients who died and 1.51 for those who survived), leading to a total of 813 168 hospital stays. The mean age was 78.0±11.4 years, 47.1% were women, the

mean CHA₂DS₂-VASc score was 4.0±1.8 and the mean HAS-BLED score was 2.2±1.1. Half of the patients (50.2%, n=267 681) were hospitalised for a cardiovascular reason (table 1). The cardiac diagnoses leading to hospitalisation were, in decreasing frequency, dysrhythmia (22.5%), heart failure (18.3%), vascular and ischaemic diseases (7.1%), stroke/transient ischaemic attack (TIA)/systemic embolism (SE) (6.8%) and haemorrhage (1.3%) (table 1).

During hospitalisation, 9.4% (n=50 165) of the patients died. These patients were older than those who survived, had a higher prevalence of comorbid conditions and risk factors, and were at higher risk of a stroke or a bleed according to their CHA₂DS₂-VASc and

HAS-BLED scores (table 2). The three most common reasons for hospitalisation in the patients who died were for a lung condition, heart failure or stroke/TIA/SE (table 1). Thirty-four per cent (n=17 066) of the in-hospital deaths were due to a cardiovascular event (table 3), most commonly heart failure (16.6%), stroke/TIA/SE (9.8%) and vascular or ischaemic disease (4.0%) (table 3).

The overall median length of hospitalisation was 6 (IQR 2–12) days (6 (2–12) days among survivors and 8 (3–16) days among those who died). The median lengths of hospitalisation were 8 (3–15) days for patients who had a cardiovascular death and 9 (3–17) days for non-cardiovascular death.

Determinants of death

Age ≥75 years was the strongest determinant of death on multivariable analysis in the overall population. This was followed by non-cardiovascular factors such as renal failure, cancer, lung disease, age 65–74 years, neurological disease, alcohol-related diagnosis and anaemia (figure 1). The only major cardiovascular predictor was heart failure, which was associated with a 26% increased risk of death. Female gender and vascular disease were marginally associated with risk of death, whereas history of thyroid disease and hypertension were associated with a lower risk of death. Significant interactions were found between age and four variables (cancer, renal failure, alcohol-related diagnoses and lung disease), and between sex and anaemia (all p<0.0001; see online supplementary table S2), with the interaction between age and cancer having the greatest magnitude (interaction test 834, p<0.0001), but the interaction did not drastically change the conclusions of the multivariable analysis (see online supplementary table S2). When focusing multivariable analysis on the 17 066 cardiovascular deaths, determinants were similar, with the exception of cancer, neurological disease, alcohol-related diagnoses and anaemia, which were no longer significant (figure 2). Significant interaction was found between age and renal failure (interaction test 256, p<0.0001).

Among the 95 655 patients with AF hospitalised for heart failure (see online supplementary table S3), 8.7% (n=8316) died. Variables associated with in-hospital death in this population included older age, cancer, liver or renal failure, lung or neurological diseases, anaemia, history of heart failure and valvular disease/surgery (table 4). Thyroid disease and other ischaemic heart disease were associated with a lower risk of death.

Substantially fewer patients (n=19 909) were hospitalised for an ischaemic stroke (see online supplementary table S4), of whom 13.1% (n=2614) died during hospitalisation. Factors associated with death after an ischaemic stroke were advanced age (≥65 years), female sex, lung diseases, peripheral artery disease, renal failure and heart failure (table 5).

Patients hospitalised with intracranial haemorrhage (see online supplementary table S5) were at much

DISCUSSION

This study was based on data from over half a million hospitalised patients with AF in France (of an estimated 600 000 to 1 000 000²), of whom nearly 10% died. The most common cause of death was a fatal cardiovascular event, occurring in 34% of patients. Despite the high mean CHA₂DS₂-VASc score (4.6 ± 1.6), only 9.8% of the deceased patients had a fatal stroke or SE.

The patients in our study were older than those in the international GARFIELD-AF registry¹⁸ (78.0 ± 11.4 vs 70.2 ± 11.2 years, respectively), with a greater percentage of women (47.1% vs 43.2%) and a higher mean

CHA₂DS₂-VASc score (4.0 ± 1.8 vs 3.2 ± 1.6). These dissimilarities are likely to be due to differences in the study populations: while the GARFIELD-AF enrolled patients newly diagnosed with AF at risk of stroke across the spectrum of treatment settings, our study concerned hospitalised patients with AF. Our population more closely resembles that in the nationwide US Outcomes Registry for Better Treatment of Atrial Fibrillation (ORBIT-AF), in which the median age was 75 years (IQR 67–82 years), the mean CHA₂DS₂-VASc score was 3.9 ± 1.8 , 29.4% had diabetes and 32.5% had heart failure; however, the rates of hypertension (83.0%) and previous myocardial infarction (15.8%) were higher than in our study.¹⁹

Conversely, patients in clinical trials are subject to selection bias and do not, therefore, reflect the spectrum of patients treated in practice.²⁰ Women and the elderly have been under-represented in phase III studies involving non-vitamin K antagonists, whereas diabetes, hypertension, heart failure and previous myocardial infarction were more prevalent than in the registry settings, largely due to the selection of patients with AF with one or more additional risk factors for stroke.^{18 21} Therefore, national population-based studies such as BALZAC—while subject to confounding—provide more accurate information about the profiles of patients with AF treated in routine clinical practice in their respective countries, and should provide more precise insights into the factors associated with hospital death in patients encountered in practice.

In this analysis of patients with AF, most of whom had a significant associated comorbid condition, 1 in 10 died during hospitalisation; this is in agreement with the results from other nationwide studies.^{5 22} The rate may

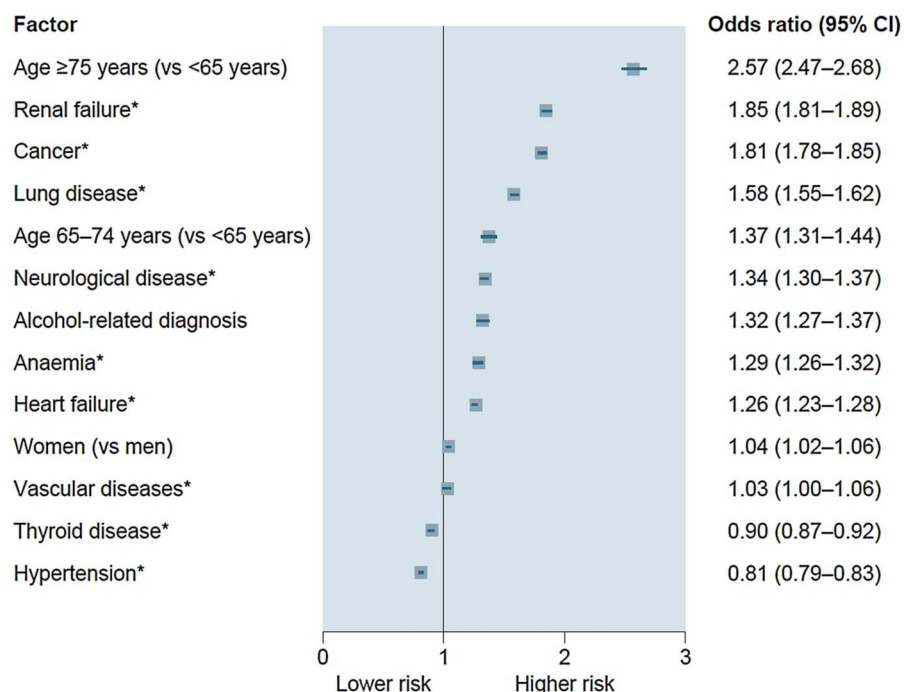

Figure 1 Determinants of death on multivariable analysis (all $p < 0.0001$). *Reference is absent disease or condition.

Figure 2 Multivariable analyses of risk factors for overall cardiovascular death (all $p < 0.0001$). *Reference is absent disease or condition.

appear higher than that reported by Patel *et al.*²³ in an analysis from the US Nationwide Inpatient Sample (hospital mortality rate 1%, rising to 2% for those aged ≥80 years); however, the rate increased to 10% in the subgroup of patients with a history of heart failure, which is indirectly similar to our finding. The rate of cardiovascular deaths in hospitalised patients with AF (34.0%) could be viewed as being somewhat similar to

the rates reported for the general population in the USA (31.3%)²⁴ and in France (27.5%).²⁵ As such, AF could simply reflect cardiovascular ageing, and would therefore be representative of general population trends rather than being specific to those with AF. It is, however, unrealistic to compare our patients to the general population, as hospitalised patients with AF are primarily elderly individuals with coexisting conditions

(whether cardiovascular, such as stroke, or non-cardiovascular, such as cancer and lung disease) that place them at increased risk of dying.

Independent predictors of mortality

Older age (≥75 years) was the strongest predictor of overall death in our study, similar to the findings in the

Framingham Heart Study in patients with new-onset AF ((HR) for stroke or death 2.13, 95% CI 1.89 to 2.40 per 10-year increase).²⁶ Age as a predictor of mortality was followed by renal failure, cancer and lung diseases. In contrast, in a post hoc analysis of deaths from the RE-LY trial database, which reported an annual mortality rate of 3.84%,¹² non-fatal major haemorrhage, non-fatal

Table 6 Univariate and multivariable analyses of risk factors for death after an intracranial haemorrhage

AF, atrial fibrillation.

stroke, heart failure and reduced renal function were the strongest predictors of overall mortality.¹² These differences are not surprising, taking into consideration the profiles of the two populations. All of the patients in the present study were hospitalised and were considerably older than those selected for the RE-LY trial¹² (mean 78.0 vs 71.5 years), which may in part explain the greater representation of women; and participants who died were on average 8 years older (82.3±9.3 years in the present study vs 73.7±9.4 years in RE-LY). The patients who died in RE-LY also had higher prevalence of diabetes mellitus (30.9% vs 26.7%), hypertension (76.7% vs 73.0%) and heart failure (47.8% vs 41.8%), but they also had a much lower prevalence of cancer (12.7% vs 30.2%). Consequently, the causes of death show substantial differences, with a 34% rate of cardiovascular death in the present study compared with a 61.4% rate in RE-LY.¹²

In our study, thyroid disease and hypertension were protective against death. It is likely that patients with thyroid disease or hypertension were being monitored closely by their physicians and were receiving appropriate therapies that lowered their risk of death. They may also have been more aware of their increased risk and were adhering to guidance about adopting a healthy lifestyle. Indeed, only 10% of the patients died from thromboembolic causes despite a high CHA₂DS₂-VASc score, and it is possible that these patients were being closely monitored for their anticoagulation status. Our findings are supported by other studies, in which various treatments and medications (including statins, β-blockers, oral anticoagulant use, ventricular pacing), as well as hypertension, were protective against mortality.^{12 27}

Cause-specific cardiovascular mortality

The strongest predictor of heart failure death was age ≥75 years. Several comorbid conditions were associated with death, including renal failure, liver, lung and neurological diseases, along with cancer and anaemia. A history of heart failure and valvular disease/surgery were also independent predictors. As for overall mortality, thyroid disease was protective in our analysis, and may be a proxy for the use of appropriate therapies and better continuity of care, which lowered their risk of death.

Independent predictors of fatal ischaemic stroke included older age, lung disease and renal failure. Cardiovascular-related predictors were peripheral artery disease and heart failure. Female sex was also predictive of fatal stroke, as shown in other studies in which women were at higher risk of stroke when compared with men.^{28 29} This finding lends further support to the inclusion of female gender in the CHA₂DS₂-VASc score.¹⁵

Age >65 years, lung diseases, valvular disease/surgery and anaemia were associated with fatal intracranial haemorrhage. Previous intracranial haemorrhage was

protective against a fatal intracranial haemorrhage, and may reflect 'survivors' of this event, who have a higher probability of survival due to their increased awareness of the symptoms and ongoing management. These findings contrast with the RE-LY study, in which non-fatal stroke during follow-up was the only significant predictor of haemorrhage-related death.¹²

Interestingly, some of the predictors were the same for all three causes of death, but some were more specific, and these findings are among the new insights from our analysis.

Limitations

As a retrospective analysis, the study is subject to the normal limitations of such studies. The cohort comprises hospitalised patients, who are at higher risk than non-hospitalised patients. Second, the analysis is limited to deaths that occurred during hospitalisation, and the results cannot be generalised to patients who died before hospitalisation or after discharge. However, French data show that hospital deaths account for 66% of all deaths in patients aged 70–80 years, similar to the mean age of our population.³⁰ Our study, therefore, provides important insights into the reasons why patients with AF die.

The study data were collected retrospectively and are also, by definition, subject to classification bias. Some minor diagnoses may have been under-reported in the database because of a lack of incentive for the hospital to exhaustively report every case, while others may have been misclassified. However, this registry has been adopted by the health authorities as the principal index for budget allocation in French public hospitals, and the quality of information in the PMSI databases has improved dramatically over recent years. Indeed, patients from the present study showed a prevalence of chronic diseases and antecedents close to those reported in other observational studies.^{18 31} Furthermore, the reliability of the PMSI data has been assessed,^{32 33} and this information has been used to study patients with stroke,¹³ myocardial infarction³⁴ and AF.² The results may not be generalisable to the general population since a known comorbidity with AF or atrial flutter, and perhaps oral anticoagulation and other underlying cardiac conditions, may have led to a lower threshold for hospital admission. No information was available for medications, in particular anticoagulation or medications for heart failure, in this national database. This limitation does not alter the results on cause of death in patients with AF, but the availability of cardiovascular treatments, including oral anticoagulant therapies for stroke prevention and treatments for heart failure, would be of major interest for future research on predictors of death in this specific population. The rate of anticoagulant use in France at the time this study was conducted is estimated to be approximately 80%, according to registries,^{31 35} but the rate is likely to be lower in unselected patients. Finally, our analysis

included every AF diagnosis, irrespective of whether it was the primary reason for hospitalisation or a coexisting condition.

CONCLUSIONS

Cardiovascular events were the most common cause of death in patients hospitalised for AF in France, occurring in 34% of patients. Despite the high risk of stroke in this population, only 9.8% died from stroke/TIA/SE. Optimal management is necessary, including the use of evidence-based cardiac medications, to reduce the risk of death in hospitalised patients with AF.
