Increase in the intake of refined carbohydrates and sugar may have led to the health decline of the Greenland Eskimos

James J DiNicolantonio

Recently, Fodor et al performed a systematic review to determine if the claims made by Bang and Dyerberg in the 1970s were true that the Greenland Eskimo had a low incidence of coronary artery disease. The authors concluded, ‘The results of these investigations confirm that the prevalence of CAD in Inuits (Eskimos) is as high or higher compared to non-Eskimo populations’. Almost all of the evidence that was gathered by Fodor et al’s systematic review came from 1979 or afterwards. Based on the evidence, there can be little doubt that the Greenland Eskimos were indeed at a similar or even greater risk of atherosclerosis or coronary artery disease. However, the authors did find one study, from the late 1940s, that confirmed a lower risk of atherosclerotic disease in the Greenland Eskimo. Since western foods have been known to negatively impact the health of numerous isolated societies, the author decided to investigate what dietary changes may have occurred that might explain the increase in atherosclerotic disease in the Greenland Eskimos.

When looking at earlier evidence, there were two main publications discovered by Fodor et al that they considered as level of evidence I (the highest level of evidence), which were ‘based on actual investigation, clinical, autopsies imaging techniques’. Oddly enough, these two reports from the 1940s came to opposite conclusions, one in supporting the notion that the Greenland Eskimos had less atherosclerosis (Ehrstrom), and one suggesting a similar or greater prevalence in the Eskimos (Bertelsen).

To address the supportive evidence first, Ehrstrom studied Eskimos in the same region as Bang and Dyerberg (Umanak district), which makes his findings a relevant comparison. Ehrstrom measured ‘sclerosis’ in 1071 Eskimos (531 women and 540 men) from Umanak district in North Greenland, and 857 people from Korpo, Finland, between 1948 and 1949. To be included in the group of sclerotic, one or more of the following symptoms had to be present: ‘palpable arteriosclerosis, roentgenological elongation, dilation or calcification of the aorta, enlargement of the heart with or without coronary insufficiency not congenital or due to infection, intermittent claudication and cerebral apoplexy (haemorrhage or thrombosis)’.

Ehrstrom found that the number of sclerotics was about four times lower in the Eskimos of Umanak (7.5%, 80/1073) than in Korpo, Finland (29%, 300/887). When broken down by age, in those over 40 years, there were twice as many sclerotics in Korpo Finland versus the Umanak Eskimos (51% vs 25%), and in those over 50 years, there were almost four times as many (36.4% vs 10.5%). Ehrstrom concluded, ‘With this age-distribution Korpo might be expected to have 2 or 3 times more sclerotics than Umanak… In no circumstances however, can it be denied that the incidence of clinical manifestations of arteriosclerosis, in relation to the age-distribution, is lower in Umanak in North Greenland than in the Korpo District in the southwest of Finland’. Ehrstrom also took blood pressures from the same sample and wrote, ‘Arterial hypertension of the malignant nephrosclerotic type has never been diagnosed in North Greenland and essential hypertension is rare except for the type pseudohypertension’. In summary, from a study of over 1000 Greenland Eskimos in the late 1940, the rate of atherosclerotic disease was apparently low (7.5%), about 2–3 times lower than that in Finland at the time.

Thus, it can be assumed that the health of the Greenland Eskimos began to decline in the early 1900s, when the level of atherosclerotic disease reached a level similar to or worse
than that of other western countries by the late 1970s. It was then discovered by this author that carbohydrate intake in the diet of the Greenland Eskimos (calculated in 1855 by Rink) went up from only 2–8% to 40% in the Greenland Eskimos who were studied by Bang et al in the 1970s (over half of the carbohydrates coming from refined sugar). In fact, in 1855, the intake of refined sugar in the Greenland Eskimos was just 6 g/person/day, increasing to 164–175 g/day by the 1970s. When Dyerberg and colleagues visited the Eskimos, they noted that the Eskimos had ‘terrible teeth from their habit of sipping their coffee through a sugar cube’. The dietary intake of the Umanak Eskimos, which was documented by Bang et al and published in 1976, was calculated from 7 consecutive days of food intake. All meals were collected and weighted from seven Umanak Eskimos who were asked not to change their habitual diet. All foods were weighed, homogenised and aliquots were frozen until these could be analysed in Denmark. The average daily consumption of sugar in these Greenland Eskimos was noted as 164 g/day, 134 g of bread, biscuits and rye flour, 31 g rice, and 42 g potatoes. This equates to 371 g of carbohydrate per day. A similar study, but this time looking at the dietary intake of 50 Greenland Eskimos, was carried out by Bang et al, and it found similar results, thus strengthening their prior dietary intake estimates. The high-carbohydrate western foods consumed by these Eskimos came from a shop run by the Royal Greenland Trading Company, where the primary foods available were bread, biscuits, sugar, margarine, potatoes, rice, coffee, tea, milk powder, flour and beer. In fact, by the 1920s and particularly after the early 1900s, which would explain why Bertelsen noted a similar or even greater incidence of atherosclerosis in the Greenland Eskimos whom he studied. Table 1 summarises how an increase in the intake of refined carbohydrate and sugar paralleled the rise in atherosclerotic disease in the Greenland Eskimos.

The contradictory evidence by Bertelsen indicating that the Greenland Eskimos had a similar or greater incidence of atherosclerosis at face value was discouraging to the notion that the Greenland Eskimos were indeed healthier than the people in the western world. However, according to Bertelsen, the consumption of sugar (and chocolate) in West Greenland went up from just 11 lbs per person per year in 1901–1903 to 87 lbs per person per year by 1930–1933. When dyeberg and colleagues visited the Eskimos, they noted that the Eskimos had ‘terrible teeth from their habit of sipping their coffee through a sugar cube’. The dietary intake of the Umanak Eskimos, which was documented by Bang et al and published in 1976, was calculated from 7 consecutive days of food intake. All meals were collected and weighted from seven Umanak Eskimos who were asked not to change their habitual diet. All foods were weighed, homogenised and aliquots were frozen until these could be analysed in Denmark. The average daily consumption of sugar in these Greenland Eskimos was noted as 164 g/day, 134 g of bread, biscuits and rye flour, 31 g rice, and 42 g potatoes. This equates to 371 g of carbohydrate per day. A similar study, but this time looking at the dietary intake of 50 Greenland Eskimos, was carried out by Bang et al, and it found similar results, thus strengthening their prior dietary intake estimates. The high-carbohydrate western foods consumed by these Eskimos came from a shop run by the Royal Greenland Trading Company, where the primary foods available were bread, biscuits, sugar, margarine, potatoes, rice, coffee, tea, milk powder, flour and beer. In fact, by the 1920s and particularly after the early 1900s, which would explain why Bertelsen noted a similar or even greater incidence of atherosclerosis in the Greenland Eskimos whom he studied. Table 1 summarises how an increase in the intake of refined carbohydrate and sugar paralleled the rise in atherosclerotic disease in the Greenland Eskimos.

In conclusion, an increase in the intake of refined carbohydrate and sugar paralleled the rise in atherosclerotic disease in the Greenland Eskimos. While the total carbohydrate intake of the Greenland Eskimos was just 2–8% of total calories in 1855, this increased to around 40% of calories by 1955. The Greenland Eskimos studied by Bang and Dyerberg in the 1970s no longer consumed a traditional healthy Eskimo diet. Indeed, the intake of refined sugar in the Greenland Eskimos increased by almost 30-fold from 1855 (6 g/person/day or around 1½ teaspoonful of sugar) to the 1970s (164–175 g or around 40–44 teaspoonful of sugar). Moreover, the intake of refined carbohydrate increased 5–7-fold from 1855 (18 g/day from bread) to the 1970s (84–134 g/day from bread, biscuits and rye flour).

In summary, the intake of refined carbohydrate and sugar by the Greenland Eskimos increased in parallel to the rise in atherosclerotic disease. Considering that a similar event occurred in the USA and that the overconsumption of refined sugar is a principal driver of type 2 diabetes, hypertension and coronary heart disease, this most likely explains the health decline of the Greenland Eskimos.
