ABSTRACT

Objective Approximately 3.4% of adults aged >75 years suffer from aortic stenosis (AS). Guideline indications for aortic valve replacement (AVR) distinguish between patients with symptomatic and asymptomatic severe AS. The present analysis aims to assess contemporary practice in the treatment of severe AS across Europe and identify characteristics associated with treatment decisions, namely denial of AVR in symptomatic patients and assignment of asymptomatic patients to AVR.

Methods Participants of the prospective, multinational IMPULSE database of patients with severe AS were grouped according to AS symptoms, and stratified into subgroups based on assignment to/denial of AVR.

Results Of 1608 symptomatic patients, 23.8% did not undergo AVR and underwent medical treatment. Denial was independently associated with multiple factors, including severe frailty ($p=0.024$); mitral ($p=0.002$) or tricuspid ($p=0.004$) regurgitation grade III/IV, and the presence of renal impairment ($p=0.017$). Of 392 asymptomatic patients, 86.5% had no prespecified indication for AVR. Regardless, 36.3% were assigned to valve replacement. Those with an indexed aortic valve area (AVA; $p=0.045$) or left ventricular ejection fraction (LVEF; $p<0.001$) below the study median; or with a left ventricular end systolic diameter above the study median ($p=0.007$) were more likely to be assigned to AVR.

Conclusions There may be considerable discrepancies between guideline-based recommendations and clinical practice decision-making in the treatment of AS. It appears that guidelines may not fully capture the complete clinical spectrum of patients with AS. Thus, there is a need to find ways to increase their acceptance and the rate of adoption.

INTRODUCTION

Recent recommendations on the treatment of aortic stenosis (AS) distinguish between

Key questions

What is already known about this subject?

► In 2012, the European Society of Cardiology produced guidelines that included a class I recommendation for aortic valve replacement in all patients presenting with symptomatic aortic stenosis (AS). These guidelines were updated in 2017 to include all patients with symptomatic AS with high-gradient AS or low-flow, low-gradient AS, a reduced left ventricular ejection fraction and evidence of contractile reserve.

What does this study add?

► Our study assessed the contemporary decision-making process for the treatment of patients with severe AS across European treatment centres. We showed that 23.8% of patients with symptomatic AS did not undergo treatment and treatment denial was associated with severe patient frailty, mitral/tricuspid regurgitation grade III/IV and renal impairment. Conversely, 36.3% of patients with no prespecified indication for aortic valve replacement were assigned treatment.

How might this impact on clinical practice?

► There appears to be discrepancies between guideline-based recommendations and clinical practice decision-making for treatment of patients with severe AS and a significant percentage of symptomatic patients with severe AS are not being offered life-saving treatment. Guidelines may not fully capture the complete clinical spectrum of patients with AS. Thus, there is a need to find ways to increase their acceptance and the rate of adoption.

patients with symptomatic and asymptomatic severe AS. The 2012 European Society of Cardiology guidelines featured a class-I

recommendation for aortic valve replacement (AVR; either surgical aortic valve replacement (SAVR) or transcatheter aortic valve implantation (TAVI)) in all patients presenting with symptoms.¹ This was updated in 2017 to include all symptomatic patients with high-gradient AS or low-flow, low-gradient AS, a reduced left ventricular ejection fraction (LVEF) and evidence of contractile reserve.² A class IIa recommendation remains for those with low-flow, low-gradient AS, a reduced LVEF and no flow reserve, and those with a paradoxical low-flow low-gradient AS.² In patients with asymptomatic AS, AVR should be performed in patients with a LVEF <50% and a pathological exercise test.^{1,2} AVR is also recommended in asymptomatic patients with a peak transvalvular velocity ($V_{\max}$) of >5.5 m/s^{1,2} and/or severe pulmonary hypertension.² Generally, a careful risk–benefit analysis by the heart team is advocated prior to AVR in any asymptomatic individual due to recent evidence of a potential benefit of AVR versus medical therapy in asymptomatic patients.³ While guidelines recommend best clinical practice according to the available evidence, real-world deviations are known to occur. Furthermore, contemporary data on the real-world management of patients with AS are scarce. Historical data demonstrated that 33%–41% of patients did not undergo SAVR in the past—despite severe symptomatic AS.^{4,5} Recently, the widespread availability of TAVR has opened a less invasive treatment option for higher risk patients and the process of decision-making within the heart team approach has changed in many European centres. It is timely, therefore, to assess the contemporary practice of decision-making in patients with severe AS in centres across Europe in the era of interdisciplinary TAVI treatment. The present analysis aims to explore the characteristics of patients with severe AS with unusual treatment decisions, namely severe symptomatic patients did not undergo AVR and asymptomatic patients assigned to AVR, and to identify potential reasons for it.

METHODS

Originally designed as part of a quality-of-care initiative, IMPULSE is a prospective, multinational registry of patients with severe AS across Europe. It was funded by Edwards Lifesciences (Nyon, Switzerland) and sponsored by the Institute for Pharmacology and Preventive Medicine (Cloppenburg, Germany). The authors are solely responsible for the design and conduct of this study, all study analyses and drafting and editing of the paper.

The rationale and methodology of the registry has been previously described.^{6–8} Patients were enrolled between March 2015 and April 2017 at 23 centres across nine European countries (Austria, Czech Republic, France, Germany, Italy, the Netherlands, Spain, Switzerland and the UK). All sites offered the full range of treatment options for AS, including surgical and transcatheter procedures. All patients provided their written informed consent to participate.

On a centre basis, consecutive patients aged over 18 years being diagnosed with severe AS (symptomatic or asymptomatic) defined as an aortic valve area (AVA) <1 cm², indexed AVA <0.6 cm²/m², $V_{\max}$ >4 m/s, or mean transvalvular gradient >40 mm Hg following echocardiography were included. Prior AVR recipients were excluded.

Details were documented by each centre (echocardiographer or a nurse under their supervision) and included patient demographics, medical history, disease characteristics and symptoms at presentation (chest pain, shortness of breath and/or dizziness on exertion/syncope) were entered into an electronic case report form. Canadian Cardiovascular Society-defined angina class III/IV and New York Heart Association (NYHA) functional class III/IV were also recorded. Patients were defined ‘symptomatic’ if they presented with either chest pain, shortness of breath and/or dizziness on exertion/syncope. Echocardiographic parameters (eg, mean pressure gradient (MPG) and AVA) were documented for each patient, as was the presence of concomitant valve disease or regurgitation. As an indicator of surgical risk, a EuroSCORE II value was calculated for each patient. Frailty was defined as ‘none’ (able to walk five metres in under 6 s plus independent activities of daily living (ADL) – wash, dress, feed, toilet), ‘mild’ (unable to walk 5 m in under 6 s or fails to perform one ADL) or ‘severe’ (indicated by an inability to perform two or more ADL).⁹ Heart teams were involved in the AVR decision in the participating centres, respectively. These teams were established by each centre leveraging the expertise of cardiologists, cardiac surgeons, imaging specialists, anaesthesiologists and other if needed.

Data are presented descriptively, with continuous variables given as means with SD and categorical variables presented as absolute values with percentages (%). Group comparisons were made using a Pearson’s χ^2 or Fisher’s exact test for categorical variables and a t-test or Mann-Whitney-Wilcoxon test for continuous variables. Separate logistic regression analyses were carried out to determine baseline variables associated with AVR denial in symptomatic patients and AVR assignment in asymptomatic patients. In the former case and according to the findings of the univariate analysis, multivariate OR, 95% CI and p values were adjusted for age, severe frailty, renal insufficiency, chronic obstructive pulmonary disease (COPD), $V_{\max}$, mean AV gradient, LVEF, mitral regurgitation grade III/IV and tricuspid regurgitation grade III/IV. In the latter case, these parameters were adjusted for age, diabetes, atrial fibrillation, mean AV gradient, LVEF, pulmonary artery systolic pressure (PASP), aortic regurgitation grade III/IV and mitral regurgitation grade III/IV. All continuous variables were converted to binary predictors for regression analysis, taking the median of the overall study population as a cut-off.

All statistical analysis was performed using SPSS V.24.0 (IBM Corp.), with a p value of <0.05 considered statistically significant.

Figure 1 Patient flow. SAVR, surgical aortic valve replacement.

RESULTS

A total of 2171 patients were enrolled in the registry, of which 1743 were symptomatic and 428 asymptomatic at presentation (figure 1).

Symptomatic patients who were assigned to medical treatment were slightly older and had a higher mean EuroSCORE II compared with those assigned to AVR, with a higher proportion being severely frail and assessed to have a reduced life expectancy at baseline (table 1). Renal insufficiency and COPD were also more common among those that did not undergo AVR. In symptomatic patients, shortness of breath was the most common symptom recorded with slightly higher rates in those with an AVR (92.7%) than in those without (86.2%). Other symptoms, such as dizziness/syncope and chest pain, were equally frequent in those with or without an intervention (figure 2A). Medically treated symptomatic patients had a larger indexed AVA, lower V_{max} , lower mean AV gradient and higher LVEF; however, mitral and tricuspid regurgitation grade III/IV were more frequent among those that did not undergo AVR, as was the combination of an AVA $< 1 \text{ cm}^2$ plus a mean AV gradient $< 40 \text{ mm Hg}$ (table 2). A definitive decision for either medical treatment or AVR was made in 1608 (92.3%) of symptomatic patients: 1225 of these patients were assigned to any AVR (810 TAVI and 415 SAVR) and the rest assigned to medical treatment (figure 1). The decisions not to perform AVR despite symptomatic AS were made by a

cardiologist in 50.9% and requested by the patient in 15.4%. A heart team was involved in a 'no AVR' decision in 17.8% of cases (figure 2). Conversely, the decision to perform AVR in symptomatic patients was made by the heart team in the majority of cases (68.2%). The proportion of symptomatic patients with a class I (95.0% vs 94.4%) or class II (5.0% vs 5.6%) indication for AVR did not differ between those that did not undergo and those assigned to AVR ($p=0.168$). In a multivariate analysis, the referral by a cardiologist, shortness of breath, NYHA class III/IV and indexed AVA $\leq 0.39 \text{ cm}^2/\text{m}^2$, an LVEF $\leq 58\%$ were associated with a reduced rate of AVR denial (table 3). On the other hand, age > 80 years, severe frailty, renal impairment, mitral regurgitation grade III/IV, tricuspid regurgitation grade III/IV and interventricular septum $> 13.3 \text{ mm}$ were all associated with an increased risk of AVR denial.

The baseline characteristics of asymptomatic patients assigned to AVR were comparable to those assigned to medical treatment (table 1). In patients undergoing medical treatment, diabetes was more frequent but it did not reach statistical significance. Asymptomatic patients assigned to AVR had a smaller indexed AVA and a higher V_{max} (table 2). Mean LVEF was slightly lower (although still within the normal range) and PASP was significantly higher in patients assigned to medical treatment. A definitive treatment decision was made in 392 asymptomatic patients (91.6%); 52 of these 392 patients

had an indication for AVR according to guideline-based criteria (2017: LVEF <50%, V_{max} >5.5 m/s, pulmonary hypertension >60 mm Hg), though such a procedure was planned in just 30 cases (22 were scheduled for TAVI, 8 for SAVR) (figure 1). Of the remaining 339 patients with no prespecified indication for AVR, 123 were assigned to TAVI or SAVR. The heart team was responsible for the majority of AVR assignments in asymptomatic patients (53.9%), while cardiologists were responsible for the majority of the decisions not to perform AVR (68.5%) (figure 3). Patients undergoing AVR had a guideline-confirming indication in 18.3% (guidelines from 2012) and 19.6% (guidelines from 2017) of cases. LVEF <50% was the most common reason (15.3%) named as a reason for the intervention. Conversely, this means that between 80.4% and 81.7% of those undergoing AVR had no guideline-based indication. On the other hand, 8.4% and 9.2% patients not undergoing AVR had a guideline-based indication. An indexed AVA, a LVEF below the median of the study population, or a left ventricular end systolic diameter (LV-ESD) above the median were predictive for AVR assignment (table 4). Conversely, renal impairment reduced the likelihood of an asymptomatic patient being assigned to AVR.

DISCUSSION

In the present study, almost a quarter (23.8%) of patients with severe symptomatic AS did not undergo AVR. Age >80 years, severe frailty and the comorbidities renal impairment (CCR <50 mL/min or dialysis) and concomitant mitral/tricuspid valve regurgitation were all found to be independent deterrents for AVR in this subpopulation. Further, the absence of dyspnoea and a larger AVA, lower MPG and lower V_{max} despite severe AS were associated with a medical treatment decision. Interestingly, symptomatic patients with a lower surgical risk were also less likely to be assigned to AVR. Conversely, over one-third (36.3%) of asymptomatic individuals with no predesignated indication for AVR were assigned to undergo treatment (with TAVI planned in over half of these cases); very few variables were associated with this treatment decision.

Treatment denial and not adhering to guideline recommendations for patients with symptomatic AS is not uncommon (range 21%–41%),^{4 5 10} and our results support these findings. Fortunately, the number of patients not being treated has reduced over time, which may be attributed to the adoption of TAVI as a treatment option for high-risk patients, as well as changes in decision-making by the heart team in many centres.¹¹ Nevertheless, it is crucial to understand the variables

Figure 2 Impact of (A) symptoms in symptomatic* patients and (B) guideline recommendations in asymptomatic* patients on the decision to perform aortic valve replacement (AVR). CCS, Canadian Cardiovascular Society; LVEF, left ventricular ejection fraction; NYHA, New York Heart Association; PASP, pulmonary artery systolic pressure; V_{max} , peak aortic valve (AV) jet velocity. *Symptomatic defined as having ≥ 1 of the following (presumed to be AS-related): chest pain, shortness of breath, dizziness on exertion/syncope. associated with an active decision not to perform AVR in almost one-quarter of symptomatic patients, especially as the survival prospects associated with this strategy are poor.¹²

Older age and more severe left ventricular dysfunction were found to be key drivers of SAVR denial in patients

with symptomatic AS enrolled in the Euro Heart Survey,⁴ likely due to the higher surgical risk associated with interventions in these patients.¹³ While this study found that age was associated with AVR denial, both a smaller AVA and a lower LVEF appeared to increase the likelihood of intervention by nearly twofold. This is probably a result

of recent evidence demonstrating the substantial functional recovery and mortality benefit from AVR interventions in patients with poor left ventricular function,^{13 14} with TAVI shown to be particularly safe in this population.^{15 16} In this context and given the often exacerbated symptoms in patients with a lower LVEF,¹⁷ poorer echocardiographic valve parameters may actually be viewed as an incentive for AVR, with a greater improvement in quality of life to be gained for the interventional risk and a better risk–benefit ratio. This is supported by the fact that dyspnoea appeared to be a major driver of a positive AVR decision. However, waiting for a deterioration in echocardiographic parameters and symptoms before scheduling AVR treatment increases the risk of sudden cardiac death.¹⁸

More recently, comorbidity has been highlighted as a reason for non-assignment of symptomatic patients to SAVR.¹⁹ In this study, renal impairment was identified

as an independent predictor of AVR denial in symptomatic patients, likely because pre-existing chronic kidney disease is strongly associated with worse outcomes following TAVI.²⁰ In contrast to medical management, AVR in haemodialysis patients has been shown to result in a significantly lower long-term mortality risk.²¹ Furthermore, TAVI may improve renal function,²² and reduce rates of in-hospital mortality compared with SAVR.²³ The presence of concomitant valvular disease is a substantial factor influencing the decision to deny TAVI.^{24 25} Significant concomitant mitral/tricuspid valve regurgitation were identified as independent predictors of AVR denial in symptomatic patients in our study. Both mitral and tricuspid regurgitation are known to affect functional status and prognosis in patients with AS undergoing AVR.^{26 27} There is little evidence, however, to support combined or sequential procedures to address concomitant valve conditions and modify this risk.^{2 27} As such,

All continuous variables were converted to binary predictors using the median of the overall study population as a cut off.

*Symptomatic defined as having ≥1 of the following (presumed to be AS related): chest pain, shortness of breath, dizziness on exertion/syncope.

†Adjusted for age, severe frailty, renal insufficiency, COPD, V_{max}, mean AV gradient, LVEF, mitral regurgitation grade III/IV and tricuspid regurgitation grade III/IV.

‡Creatinine clearance rate <50 mL/min or dialysis.

§Insulin dependent.

¶2-year life expectancy < 25% was assessed by the dedicated nurses and physicians.

AV, aortic valve; AVA, aortic valve area; AVR, aortic valve replacement; COPD, chronic obstructive pulmonary disease; IVS, interventricular septum; LV, left ventricular; LV-EDD, left ventricular end diastolic diameter; LVEF, left ventricular ejection fraction; LV-ESD, left ventricular end systolic diameter; NYHA, New York Heart Association; PASP, pulmonary artery systolic pressure; PW, posterior wall; V_{max}, peak AV jet velocity.

Figure 3 Entity responsible for treatment decision. AVR, aortic valve replacement; int. cardiol., interventional cardiologist. *Symptomatic defined as having ≥ 1 of the following (presumed to be aortic stenosis related): chest pain, shortness of breath, dizziness on exertion/syncope.

it is natural that mitral and tricuspid regurgitation are current deterrents to AVR. Existing knowledge gaps need to be addressed. Frailty is consistently associated with death and disability after TAVI and SAVR,²⁸ and this study showed that severe frailty was independently associated with AVR denial in symptomatic patients. Indeed, both 2012 and 2017 guidelines identify this variable as a key consideration for SAVR versus TAVI decision-making.¹²

Guidelines recognise the limitations and inaccuracies of classical surgical risk scores when assessing a patient for either intervention, although highlighting the utility of scores to predict general trends in outcomes. Interestingly, after adjustment for potentially confounding variables, a lower surgical risk score appeared to translate into a higher likelihood of AVR denial in the present population. This appears paradoxical, especially given that prior studies have noted a clear and logical association between higher EuroSCORE II values and poorer postinterventional outcomes.²⁹ Given the large number of variables entered into the regression, this finding may merely represent a statistical error, which merits further exploration.

In this study, the patient was responsible for the treatment decision in 15% of symptomatic cases not assigned to AVR. It is assumed that all patients were fully informed when making such a choice, but education programmes should stress the relative futility of medical management

compared with AVR.³⁰ Patient preference is likely to be influenced by the responsible practitioner, cardiologist and heart team. Strikingly, over half of the decisions not to perform AVR in symptomatic patients were taken by a cardiologist, with the heart team involved in just 18% of cases. This is a clear deviation from guideline recommendations, which state that the heart team should be integral to the clinical decision-making process.² Indeed, over two-thirds of positive AVR decisions were made by the heart team, suggesting that a comprehensive expert and multidisciplinary review took place, which may have resulted in a higher proportion of symptomatic patients not undergoing AVR being assigned to such an intervention. Increasing the awareness of the importance of the heart team's perspective, therefore, may increase the proportion of patients benefitting from AVR.

According to 2017 guidelines, AVR is only indicated in asymptomatic patients under specific circumstances²; present data support the use of SAVR when a patient has a LVEF $< 50\%$; a $V_{\max} > 5$ m/s or pressure difference of > 60 mm Hg; an abnormal exercise test; rapid AS progression; or progressively increasing brain natriuretic peptide values.³¹ Furthermore, only SAVR and not TAVI is advocated in this population, given only very minimal evidence for the latter intervention.³² Despite this, one-third of asymptomatic individuals with no predesignated indication for AVR were assigned to treatment, over half

§Insulin dependent.

¶2-year life expectancy < 25% was assessed by the dedicated nurses and physicians.

AS, aortic stenosis; AV, aortic valve; AVA, aortic valve area; AVR, aortic valve replacement; COPD, chronic obstructive pulmonary disease; IVS, interventricular septum; LV, left ventricular; LV-EDD, left ventricular end diastolic diameter; LVEF, left ventricular ejection fraction; LV-ESD, left ventricular end systolic diameter; PASP, pulmonary artery systolic pressure; PW, posterior wall.

of which were TAVI procedures. In terms of independent predictors, a lower AVA indexed and LVEF, a higher LV-ESD and an absence of renal impairment were associated with AVR assignment. While only LVEF is specifically stated in guidelines within the context of AS, LV-ESD is an indicator for intervention in various other valve-related conditions.^{1 2} The role of kidney insufficiency deterring invasive procedures has already been discussed.²⁰ As such, our data suggest that there are few specific characteristics

that would influence a positive AVR decision in asymptomatic patients.

LIMITATIONS

Due to the post-hoc nature of the present analysis, several factors that may potentially have contributed to treatment decisions were not available. Exercise testing, markedly elevated natriuretic peptide levels or combined severe valve

calcification and a rate of $V_{\max}$ progression ≥ 0.3 m/s/year may also have resulted in a class I or IIa indication for AVR in asymptomatic patients,¹² though this information was not systematically recorded. This may explain a large number of the asymptomatic patients assigned to AVR (including TAVI). Moreover, we did not capture specific reasons for the denial of AVR in extreme risk or inoperable patients which would have required a specific questionnaire. Furthermore, a large number of factors were considered in the regression analyses; while this is defensible given that our aim was to provide a comprehensive view of the characteristics contributing to AVR decision-making, it also increases the potential for overfitting. Finally, while the Europe-wide nature of the present study is a clear strength, our findings may not be generalisable to other countries or regions outside of Europe, or to centres where not all AS management options are available. Nevertheless, the data provide an interesting snapshot into some of the behaviours and parameters likely contributing to treatment decisions in severe AS.

CONCLUSION

The present results illustrate that almost one-quarter of patients with symptomatic severe AS with guideline indications for AVR did not undergo valve replacement, despite the poor prognosis associated with a lack of intervention. In contrast, over one-third of asymptomatic patients were assigned to AVR, with very few specific characteristics associated with this choice. We conclude that there may be a considerable discrepancy between guideline-based recommendations and clinical practice decision-making in the treatment of AS. It appears as if guidelines may not fully capture the clinical spectrum of AS presentation and the individual patient need for an intervention or that unrequired AVRs may be being performed.
